Abstract

High blood pressure (HBP) is the most common condition seen in primary care and leads to myocardial infarction, stroke, kidney failure and death if not detected early and treated adequately. Patients want to ensure that blood pressure treatment will reduce the disease burden, while clinicians want guidance for the management of high blood pressure using the best scientific evidence. High blood pressure is a global problem. The family doctor plays a significant role in prevention, early detection but also in monitoring the treatment. Current studies highlight the importance and need for family doctor involvement.

Keywords: high blood pressure, primary care, family doctor

Introduction

High blood pressure (HBP) is the most common condition seen in primary care and leads to myocardial infarction, stroke, kidney failure and death if not detected early and treated adequately. Patients want to ensure that blood pressure treatment will reduce the disease burden, while clinicians want guidance for the management of high blood pressure using the best scientific evidence. This report has a rigorous, evidence-based approach to recommending treatment thresholds, targets, and drugs to treat high blood pressure in adults. Evidence was extracted from randomized controlled trials, which are the gold standard for determining efficacy (1).

Comparable limited data are available on the prevalence of hypertension and temporal trends in blood pressure values in different European countries. In general, the prevalence of hypertension seems to amount to 30-45% of the general population, with a significant increase in patients’ number. It also appears that there are visible differences in average blood pressure levels between countries, with no systematic trends in blood pressure changes over the past decade (2).

Globally, the prevalence of hypertension is around 1 billion people, according to the WHO, which is the leading cause of death due to its consequences (3). The control of blood pressure values must be improved because, at present, it is insufficiently achieved, thus contributing to an increased level of cardiovascular morbidity and mortality (4). The SEPHAR study showed a prevalence of hypertension of 40.1% in Romania, i.e. approximately 8.8 million hypertensives (5).
ESSENTIAL ASPECTS OF DIAGNOSING HYPERTENSION IN FAMILY MEDICINE

For a correct diagnosis of hypertension, it is essential to use an appropriate blood pressure measurement technique. Improper blood pressure measurement is common and can change your blood pressure reading by up to 10 mmHg, leading to misdiagnosis and classification of hypertension.

Correct blood pressure measurement requires that the person whose blood pressure is to be measured be kept quiet for at least five minutes, followed by applying a blood pressure cuff adequately fitted to the empty upper limb. The person whose blood pressure is being measured should avoid talking or moving during this process. The measuring arm must be supported on a flat surface at the heart level (6). The bladder should be emptied before measuring a person’s blood pressure, as it can increase blood pressure by up to 15/10 mmHg. Several blood pressure values (at least two) should be obtained 1-2 minutes apart to ensure the measurement’s accuracy (7). Monitoring blood pressure amplitude from 12 to 24 hours is the most accurate method for confirming the diagnosis.

ASPECTS OF CARDIOVASCULAR RISK

The concept of cardiovascular risk is based on the idea of mutual potentiation of risk factors in the same patient so that the cumulative risk is greater than the sum of its components. It is about the estimated risk of an acute coronary event or stroke in the hypertensive population over 5 or 10 years, extremely useful in assessing the optimal time for therapeutic intervention (8).

The term “additional risk” indicates the amount of risk added to the average risk through the presence of risk factors, subclinical organ damage, diabetes mellitus, clinically manifest cardiovascular or renal disease.

The terms “low”, “medium”, “high” and “very high” risk refer to the risk of fatal or non-fatal cardiovascular event at 10 years: <15%, 15-20%, 20-30%, respectively > 30% according to Framingham criteria or cardiovascular death <4%, 5-8%, and > 8% according to SCORE criteria (10,11).

CARDIOVASCULAR RISK FACTORS IN FAMILY MEDICINE

Between 1930 and 1950 there was a great increase in the analytical tools of epidemiology and statistics applied to clinical research. This has led to the creation of more appropriate models for the study of disease associations with a wide range of anthropometric, physiological or biochemical variations, environmental with other diseases and also with socio-economic data (12).

Ageing is simply a risk factor for cardiovascular disease, especially in men over 45 and women over 55. With age, women’s advantage of low cardiovascular risk is lost before menopause. One explanation is that most cardiovascular risk factors have a higher prevalence with age. At older ages, survival is lower for women with a history of myocardial infarction. The irreversible ageing process can be delayed by a balanced diet as well as by regular physical activity (13).

Sex is a significant risk factor: for men, there is a higher risk for heart disease than for pre-menopausal women. After the onset of menopause, a woman’s risk is similar to that of a man because female hormones’ protective effect (estrogens) disappears. If other risk factors (e.g. smoking) are associated, it increases women’s risk significantly, even before menopause. The INTERHEART study showed that women experience the first acute myocardial infarction on average nine years later than men (14,15).

Hereditary-collateral history of cardiovascular disease is considered a significant risk factor in first-degree male relatives before 55 and in females before the age of 65. Risk factors (including high blood pressure, diabetes and obesity) can also be “passed on” from one generation to the next. Some forms of cardiovascular disease are more common among certain racial and ethnic groups. Most patients with high blood pres-
sure are overweight. High blood pressure is about six times more common in obese subjects than in thin men and women (16).

Obesity itself is associated with changes in hemodynamics. An increase in oxygen demand caused by excess adipose tissue (≈1.5 ml/kg per minute) requires an increase in cardiac capacity. There is also a parallel increase in blood volume. Thus, obese people have an increase in blood volume, cerebral vascular volume and cardiac output. However, obese people with a higher than optimal increase in blood pressure (e.g., hypertension) have peripheral vascular resistance that is “inadequate” or increased. Therefore, although an increase in blood pressure may contribute to an increase in blood pressure in obese people, an abnormal increase in blood pressure depends primarily on the increase in peripheral vascular resistance (17,18).

The assessment and recommendations for sedentary hypertensive patients are: physical activity can be beneficial for the prevention and treatment of hypertension and reducing cardiovascular risk and mortality. A meta-analysis of randomized controlled trials showed that aerobic endurance training reduces resting TAs and TAdS by up to 3 / 2.4 mmHg in total and even 6.9 / 4.9 mm in hypertensive participants (19). Even irregular activity and shorter duration of physical activity are associated with a 20% decrease in mortality in cohort studies, and this also applies to a measured physical condition (20).

Assessment and recommendations for hypertensive smoking patients are: while the smoking rate is declining in most European countries (where a smoking ban is effective), it is still common in many regions and groups. Studies using outpatient blood pressure monitored have shown that hypertensive, normotensive and untreated smokers have higher daily blood pressure values than non-smokers (21). In addition to the impact on blood pressure, smoking is a strong cardiovascular risk factor, and quitting smoking is probably the only way to prevent cardiovascular disease, including stroke, heart attack.

While moderate alcohol consumption may not be harmful, the shift from moderate to excessive consumption is associated with increased BP and an increased risk of stroke. The study on the prevention and treatment of hypertension (PATHS) investigated the effect of reducing BP. The intervention group had a higher reduction of 1.2 / 0.7 mmHg of blood pressure than the control group at the end of the 6-month period (22). A large amount of alcohol can also lead to supraventricular arrhythmias.

CONCLUSIONS

High blood pressure is a global problem. The family doctor plays a significant role in prevention, early detection but also in monitoring the treatment. Current studies highlight the importance and need for family doctor involvement.
