ABSTRACT

It is extremely uncommon to develop primary intracranial squamous cell carcinoma, which is typically brought on by the malignant transformation of epidermoid cysts or, less frequently, by other non-malignant epithelial cysts. We report a case of squamous cell carcinoma arise in the supra sellar region. She was operated via pterional approach. The patient was plaint of decrease in visual acuity. 6 months follow-up showed visual improvement. Intracranial squamous cell carcinoma is a rare disease whose clinical presentation, treatment, and prognosis are still unclear.

Keywords: squamous cell carcinoma, tumor epidermoid, supra sellar tumor

Introduction

Epidermoid tumors are congenital lesions that they include only ectodermal elements. They occur intracranially as a result of nests of epithelial cells remaining intracranially during embryogenesis possibly due to a failure of separation between neural and cutaneous ectoderm at the time of the neural groove closure [1]. They are rarely reported, their incidence account for 0.2% to 1.8% of brain tumors [2]. Unusually, they degenerate into squamous cell carcinoma (SCC). Epidermoid cyst mostly found in cerebellopontine angle, infratentorial middle cranial fossa, and suprasellar regions. [3] In 1912, Ernst et al, were the first one who describe SCC [1]. Garcia et al and Hamlat et al, have defined the criteria for such a malignant degeneration as follow [4,5].

1. The tumor had to be limited to the intracranial, intradural compartment.
2. There must be no extension or invasion of the tumor.
3. The presence of a benign squamous cell epithelium within the malignant tumor.
4. Exclusion of carcinoma metastasis.

Case report

A 62-year-old female patient with no medical history was referred to our department for visual loss that had persisted for 5 years. Physical examination results were normal. Visual acuity was 3/10 in the right eye and light perception in left eye.

Imagery

Brain MRI showed a lesion arising from the pituitary stalk hypo-signal on T1WI with ring contrast enhancement which compress the optic chiasm and; hypersignal on T2WI (Figure 1).

Treatment and outcome

Initially craniopharingyomas was suspected. The patient underwent pituitary function evaluation and it was in normal range. Patient was operated under general anesthesia with right pterional approach. The selection of the pterional approach was made with the objective of mitigating the potential risk of pituitary injury and not the endonasal approach was chosen nor transcallosal approach. Grosse total tumor resection was achieved. Post-operative brain Ct-scan showed the resection of the tumor with no complications (Figure 2). Histological examination revealed poorly differentiated squamous cell carcinoma (Figure 3). No postoperative complication has been seen. There was no recurrence at her 6-month follow-up. Visual acuity was 6/10 in the right eye and stationary in left eye.

Discussion

Intracranial SCC arising de novo, as seen in the current case, is even rare, and only eight cases have been published to date, none of them in the sellar region.

Physiopathology:

Intracranial carcinomas classified based on clinico-pathological presentation [5]:

1. The development of carcinoma within an epidermoid cyst or within a remnant.
2. Leptomeningeal carcinomatosis transformation
3. Benign cyst transformation

Recurrent meningitis, intraoperative foreign material introduction, or chronic inflammation of an epidermoid cyst (EC) can all contribute into intracranial SCC [6].

Epidemiology and clinical presentation:

The first case diagnosed with Intracranial SCC arising de novo was reported in 1976 by Wong et al [7]. We present the 9th patient of that entity [4,7-13]. The mean age was 42.8 years, ranging from 4 to 68 years. Cerebellopontine angle was the most common, found in four patients (50%) (Table 1). Clinical presentation of primary intracranial SCC depends on their location (Table 2), hydrocephalus and cranial nerve impaired [12].

Imagery:

Radiologically, ECs are hypodense on Brain CT scan, Hypointense on T1WI with lack contrast enhancement and hyperintense on T2 imaging and diffusion weighted imaging caused by the "T2 shine-through" effect. In malignant changes, they will have irregular margins, lack of diffusion restriction and contrast enhancement [14].

Histology:

The cystic wall include benign squamous epithelium, and the cysts have keratin and squamous epithelium without malignant cells. The squamous cell carcinomas have poorly differentiated epithelial cells with pleomorphic nuclei and stromal invasion [12]. The immunohistochemical findings indicate positive reactivity for prealbumin and cytokeratin. The ependymal cyst wall is positive immunohistochemical results for GFAP, S-100, and other glial cell markers [15]. High Ki67 index indicating a relatively aggressive disease course [14].

Treatment and outcome:

Treatment options including surgical resection alone; or surgery associated with radiosurgery, or stereotactic radiosurgery (SRS); chemotherapy alone or in combination with other treatments. Surgery with adjuvant therapy augment surviving rate [12]. The full surgical resection of the squamous cell carcinoma from the brain is impeded by the tumor's robust adherence to the brain parenchyma and cerebral vessels. Consequently, the pursuit of an aggressive tumor removal approach may lead to severe neurological deficits [16]. The advantageous effects of radiotherapy on squamous cell carcinoma in various systemic organs have been extensively documented. The radiotherapy following surgical intervention may enhance the management of intracranial squamous cell carcinoma [17]. The 5-year survival rate is only 50% after surgery and radiotherapy (Table 3).

Conclusion

Primary intracranial and sellar squamous cell carcinoma rarely occurs, usually arising from the malignant transformation of epidermoid cysts or, less commonly, other non-malignant epithelial cysts. There is a lack of consensus regarding the best approach to the management. Combination of treatments necessary to obtain the optimal outcome.

Figures

Figure 1. Brain MRI showing groisierly oval intra- and supra- sellar cystic tumoral process, same signal as cerebrospinal fluid, signal suppressed on Flair sequence and unrestricted on diffusion

sequences, with ring enhancement after injection of Gadolinium, measuring 30x2 1x22mm It compresses the optic chiasma as well as the floor of V3.

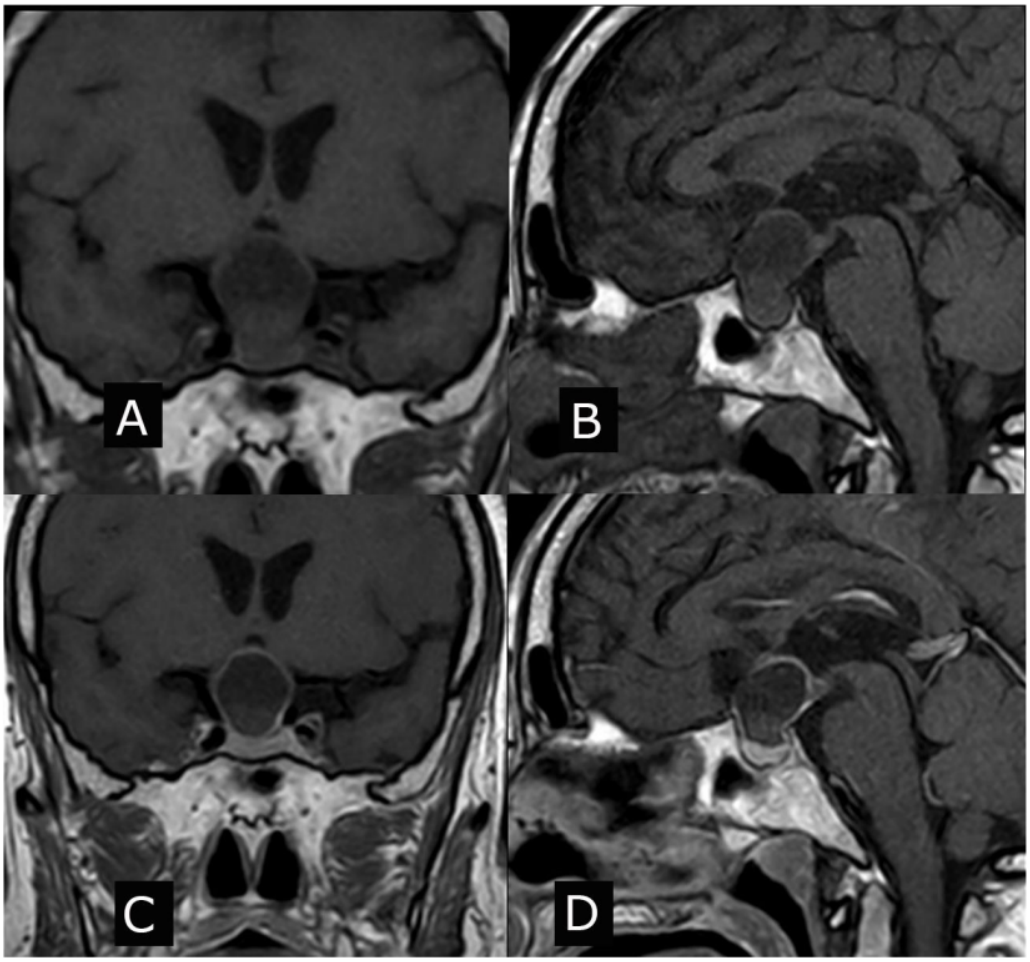

Figure 2. Postoperative CT scan illustrating gross total tumor resection without complications through the right pterional approach.

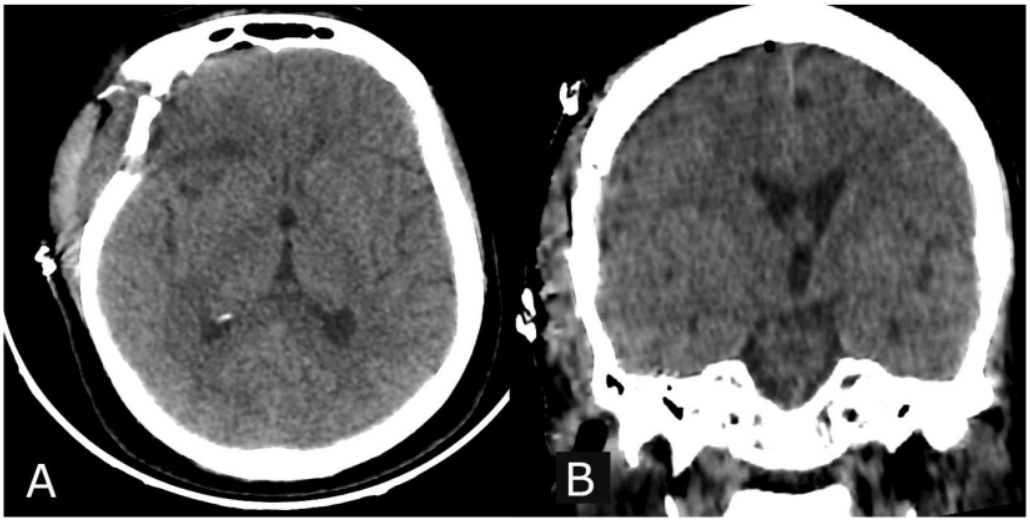

Figure 3. Microscopically, tissue is composed of large, often polyhedral cells with eosinophilic cytoplasm, more or less sharply delineated borders and clearly atypical, enlarged, hyperchromatic, anisokaryotic nuclei, sometimes nucleated and richly mitotic. These cells are often arranged in large clusters within a fibrous, inflammatory stroma.
